

Strong Lensing Source Reconstruction Using Continuous Neural Fields

Siddharth Mishra-Sharma^{1 2 3} Ge Yang^{1 4}

Abstract

From the nature of dark matter to the rate of expansion of our Universe, observations of distant galaxies distorted through strong gravitational lensing have the potential to answer some of the major open questions in astrophysics. Modeling galaxy-galaxy strong lensing observations presents a number of challenges as the exact configuration of both the background source and foreground lens galaxy is unknown. A timely call, prompted by a number of upcoming surveys anticipating high-resolution lensing images, demands methods that can efficiently model lenses at their full complexity. In this work, we introduce a method that uses continuous neural fields to non-parametrically reconstruct the complex morphology of a source galaxy while simultaneously inferring a distribution over foreground lens galaxy configurations. We demonstrate the efficacy of our method through experiments on simulated data targeting high-resolution lensing images similar to those anticipated in near-future astrophysical surveys.

1. Introduction

According to general relativity, the warping of space-time in the vicinity of a massive celestial body can distort the path of light rays traversing close-by. This phenomenon, called *gravitational lensing* (Einstein, 1936), is a powerful probe of the distribution of structures in our Universe. In the *strong lensing* regime, multiple highly magnified images of background luminous sources can be observed. This is a versatile astrophysical laboratory that has been used to characterize

distant galaxies (Wuyts et al., 2012; Yuan et al., 2017), constrain the abundance of dark matter substructures (Dalal & Kochanek, 2002; Vegetti et al., 2014; Hezaveh et al., 2016; Gilman et al., 2019; Hsueh et al., 2020; Şengül et al., 2021; Meneghetti et al., 2020), and provide percent-level estimates of the expansion rate of the Universe (Birrer et al., 2020).

A particular challenge with fully exploiting observations of galaxy-galaxy strong gravitational lenses — where an extended background source is lensed by a foreground galaxy — is that of accounting for the complex morphologies of lensed galaxies. Although sources in low-resolution images can be adequately modeled using phenomenological parameterizations such as one or several Sérsic profiles (Sérsic, 1963), this approach is inadequate for modeling higher-fidelity lensing observations such as those from ongoing, upcoming, and proposed telescopes like the *Hubble* Space Telescope (HST), JWST, *Euclid*, and the Extremely Large Telescope (ELT). The development of new methods is especially timely, given the large number of high-resolution lenses that are expected to be imaged by next-generation cosmological surveys (Collett, 2015) and their potential to weigh in on the nature of dark matter (Simon et al., 2019).

A number of methods have been proposed that go beyond using simple parameterization for the background galaxies. They include regularized semi-linear inversion (Warren & Dye, 2003), the use of truncated bases like shapelets (Birrer et al., 2015; Birrer & Amara, 2018) or wavelets (Galan et al., 2021), and the use of adaptive source-plane pixelizations (Vegetti & Koopmans, 2009; Nightingale et al., 2018). More recently, deep learning techniques, for example variational autoencoders (Chianese et al., 2020), recurrent inference machines (Morningstar et al., 2019), and Gaussian process-inspired inference (Karchev et al., 2022) have also shown promise. Downstream analyses often benefit from, and sometimes require, a probabilistic treatment of both the source and lens. Using variational methods, Karchev et al. 2022 demonstrated the ability to recover the posterior distribution over both the lens parameter and a complex source configuration.

In this paper, we explore a complementary approach for probabilistic reconstruction of complex morphologies of strongly lensed galaxies from high-resolution images while simultaneously recovering the lens mass distribution. Our

Figure 1. A schematic overview of the method used in this work.

key contribution is to treat the source-light distribution as a continuous neural field, optimized using gradient-based variational inference. Together with recovering a posterior distribution over the lens model parameters, our approach is able to infer high-resolution images of the source galaxy in its full complexity.

2. Methodology

Our proposal takes the “analysis by synthesis” approach to conduct probabilistic inference on both the source image and the lens configuration using a differentiable lensing model. We describe the three key components of this generative pipeline below: (1) the differentiable lensing model used for rendering and the relevant strong-lensing physics, (2) the continuous neural representation of the source, and (3) the variational inference procedure used to simultaneously infer the lens parameter and source posteriors.

2.1. Strong Lensing and the Synthesis Model

At the heart of our approach is a differentiable renderer that takes the source and lens configurations, and outputs modeled lensing observations. The simulator we use is a modified version of *gigalens* (Gu et al., 2022), written in Jax (Bradbury et al., 2018).

The position of the source in the lens plane θ can be evaluated using the lens equation, $\beta = \theta - \phi(\theta)$. Here β is the position in the source plane and $\phi(\theta)$ is the deflection vector, given by the gradient of the projected gravitational potential $\psi_G(\theta)$ of the lens, $\phi(\theta) = \nabla\psi_G(\theta)$. The lens equation relates the lens-plane coordinates back to those in the source-plane. Given an extended source light profile f_s and a lensing mass distribution, we can reconstruct the lens-plane observation f'_s by evaluating the source light on the lens plane, $f'_s(\theta) = f_s(\theta - \phi(\theta))$. We refer to, e.g., Treu (2010) for additional details of the strong lensing formalism.

The main lens deflector is modeled using the commonly employed *Singular Isothermal Ellipsoid* (SIE) parameterization (Kormann et al., 1994; Treu, 2010). The deflection

Table 1. List of parameters used in the lens model and their corresponding assumed prior distributions.

Parameter	Symbol	Prior
Einstein radius	θ_E	$\mathcal{U}(1'', 2'')$
Source-lens offset	$\theta_{x,0}, \theta_{y,0}$	$\mathcal{U}(-0.5'', 0.5'')$
Eccentricities	ϵ_1, ϵ_2	$\mathcal{N}(0, 0.3)$
External shear	γ_1, γ_2	$\mathcal{N}(0, 0.05)$

vector field in this case is given in terms of angular coordinates θ_x and θ_y via (see e.g., Keeton 2001)

$$\begin{aligned}\phi_{\text{lens},x} &= \frac{\theta_E q}{\sqrt{1-q^2}} \tan^{-1} \left[\frac{\sqrt{1-q^2} \theta_x}{\chi} \right] \\ \phi_{\text{lens},y} &= \frac{\theta_E q}{\sqrt{1-q^2}} \tanh^{-1} \left[\frac{\sqrt{1-q^2} \theta_y}{\chi + q^2} \right],\end{aligned}\quad (1)$$

where q is the axis ratio ($q = 1$ corresponding to a spherical lens), $\chi \equiv \sqrt{\theta_x^2 q^2 + \theta_y^2}$, and θ_E is the Einstein radius denoting the characteristic lensing scale.

The lens orientation is specified in terms of eccentricities $(\epsilon_1, \epsilon_2) = \frac{1-q}{1+q} (\cos(2\psi), \sin(2\psi))$, where ψ is a rotation angle. The large-scale lensing effect of the local environment is included through an external shear component $\{\gamma_1, \gamma_2\}$ with deflection vector $(\phi_{\text{ext},x}, \phi_{\text{ext},y}) = (\gamma_1 \theta_x + \gamma_2 \theta_y, \gamma_2 \theta_x - \gamma_1 \theta_y)$.

After allowing for an overall offset $(\theta_{x,0}, \theta_{y,0})$ between the lens and source center lines of sight, our lens mass model consists of 7 parameters $\{\theta_E, \theta_{x,0}, \theta_{y,0}, \epsilon_1, \epsilon_2, \gamma_1, \gamma_2\}$. We include the full list of lens model parameters and their assumed prior distributions in Tab. 1.

2.2. Continuous Neural Representation of the Source

In our framework, the source-light distribution is modeled using a continuous neural field $F_\Theta : \mathbb{R}^2 \mapsto \mathbb{R}^2$, which takes the source-plane coordinates $\{\beta_x, \beta_y\}$ in \mathbb{R}^2 as input and outputs the mean and variance of the light

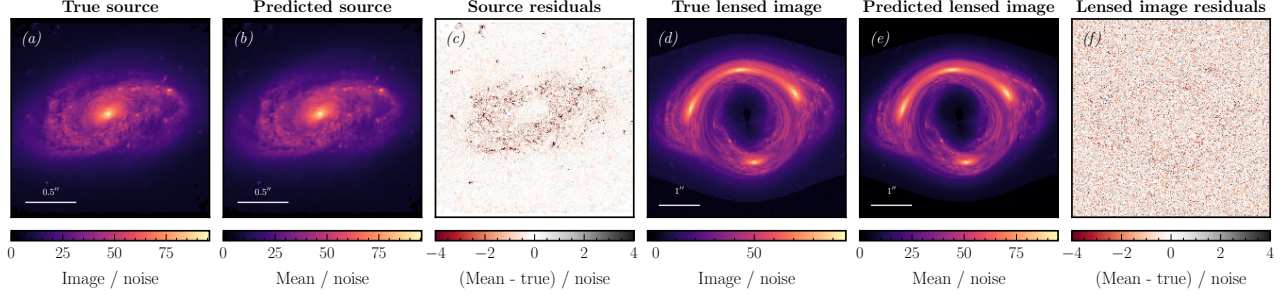

Figure 2. Results of reconstructing the source through our coordinate-based neural network pipeline using a mock lensed image of galaxy NGC2906. The (a) true source, (b) reconstructed source mean, (c) reconstructed mean minus true source residuals, (d) true lensed image, (e) reconstructed lensed image, and (f) reconstructed mean minus true lensed image residuals are shown. All images are normalized by the observation noise.

intensity, modeled as a Gaussian distribution $I(x, y) \sim \mathcal{N}(\mu_I(x, y), \sigma_I^2(x, y))$.

Based on the universal function approximation theorem (Hornik et al., 1989), a naïve choice is to parameterize F_Θ as a vanilla neural network. Although the theorem guarantees the existence of good approximations, it makes no claims of how easy or difficult it would be to attain them. Empirical analyses uncovered an intrinsic learning bias for standard network architectures to favor fitting simpler, low-spatial frequency components of the target function under gradient descent (Zhang et al., 2021; Arpit et al., 2017; Ulyanov et al., 2018; Rahaman et al., 2019). Using new tools such as the *neural tangent kernel* (NTK, Jacot et al. 2018), recent progress in deep learning theory describe this phenomena as a “spectral bias” that slows down convergence over high-frequency components of the target function exponentially, which often result in poorly-fit models (Rahaman et al., 2019; Cao et al., 2019).

This problem can be addressed by adding positional encodings, now ubiquitously used in natural language processing (Gehring et al., 2017; Vaswani et al., 2017; Devlin et al., 2018). For an input $\beta \in \mathbb{R}$, positional encodings lift the input coordinates β into a higher-dimensional spectral domain with $2 \times L_{\max}$ dimensions per input dimension:

$$\gamma(\beta) = [\sin(\beta), \cos(\beta), \sin(2\beta), \cos(2\beta), \dots, \sin(2^{L_{\max}-1}\beta), \cos(2^{L_{\max}-1}\beta)]^T, \quad (2)$$

where L_{\max} is the maximum bandwidth of the encoding. When applied to low-dimensional spaces such as image coordinates, such a scheme synthesizes high-fidelity reconstructions (Mildenhall et al., 2020), and was most recently applied in the astrophysics domain for tomographic reconstruction of lensed black hole emission in interferometric observations Levis et al. (2022). We implement F_Θ as a four-layer multi-layer perceptron (MLP) with ReLU activations and hidden dimension 256. The intrinsic modeling bias of such networks is described in detail in (Tancik et al.,

2020).

Higher values of the bandwidth hyperparameter L_{\max} encourage reconstructing higher-frequency features, but may lead to overfitting on noise. We found $L_{\max} = 5$ to work well in our set-up. Alternative schemes for lifting the input coordinates such as random Fourier features may be advantageous (Rahimi & Recht, 2008), and we discuss these in Sec. 4 and in App. A.

2.3. Variational Inference

We use variational inference (Jordan et al., 1999; Blei et al., 2017) to simultaneously fit for the joint distribution of the $n_{\text{lens}} = 7$ lens parameters alongside the source intensity distribution on a specified grid on the source plane. The variational ansatz on the lens parameters is taken to be a multivariate Normal distribution $q_{\text{lens}} = \mathcal{N}(\mu_{\text{lens}}, \Sigma_{\text{lens}})$, where μ_{lens} is the mean vector and Σ_{lens} the parameter covariance matrix. We fit for the $n_{\text{lens}}(n_{\text{lens}} + 1)/2$ -parameter lower-triangular Cholesky factor L of the covariance matrix, $\Sigma_{\text{lens}} \equiv LL^T$, ensuring positivity of the diagonal component through the projection $\text{Softplus}(\cdot) \equiv \log(1 + e^{(\cdot)})$.

The source on the other hand is modeled using a diagonal Normal distribution $q_{\text{source}} = \mathcal{N}(\mu_I, \sigma_I^2)$, with the means and variances evaluated on the source grid as the outputs of the neural network F_Θ . In this proof-of-principle exposition we do not model correlations between the lens and source parameters, leaving their inclusion to future work. In the following, the lens and source parameters (SIE parameters and intensities on a grid, respectively) are jointly denoted by ϑ .

Given a pixelized lensed image x , the source and lens variational distributions, parameterized by ϕ and jointly denoted $q_\phi(\vartheta)$, are obtained by minimizing the reverse KL-divergence between the true and variational posterior distributions, $D_{\text{KL}}(q_\phi \parallel p(\vartheta | x))$. This is done by maximizing the model log-evidence $\log p(x)$ or, in practice using the

tractable evidence lower bound (ELBO),

$$\text{ELBO} \equiv \mathbb{E}_{\vartheta \sim q_{\phi}(\vartheta)} [\log p(x, \vartheta) - \log q_{\phi}(\vartheta)], \quad (3)$$

as the optimization objective since $\log p(x) - \text{ELBO} = D_{\text{KL}}(q_{\phi} \parallel p(\vartheta \mid x))$. The expectation in the ELBO is taken through Monte Carlo sampling from the source and lens variational distributions at each optimization step. ELBO gradients are straightforwardly computed using the reparameterization trick (Kingma & Welling, 2013) since all the distributions employed are reparameterizable. We emphasize that the model only has access to the *lensed* image x and not the ground-truth source.

Monte Carlo samples from the lens and source distribution are passed through the differentiable lensing pipeline to produce lensed image samples $\{\hat{\mu}(\vartheta)\}$. The joint likelihood $p(x, \vartheta) = p(x \mid \vartheta) p(\vartheta)$ is evaluated by combining the prior with the data likelihood, modeled as Normal; $p(x \mid \vartheta) = \mathcal{N}(x \mid \hat{\mu}(\vartheta), \sigma_{\text{obs}}^2)$. Priors on the lens parameters are shown in Tab. 1.

The variational parameters—the weights and biases of F_{Θ} in the case of the source, and the mean and lower-triangular Cholesky matrix elements for the lens—are optimized using the AdamW optimizer (Kingma & Ba, 2014; Loshchilov & Hutter, 2017) over 15,000 steps. The learning rate is increased from zero to 10^{-3} over 2000 steps, then decreased via cosine annealing over the course of optimization. Fitting a lensed image typically takes ~ 20 minutes on a single Nvidia V100 GPU. The pipeline is constructed using the neural network and optimization libraries `Flax` (Heek et al., 2020) and `Optax` (Hessel et al., 2020).

A schematic illustration of the high-level features of the method are shown in Fig. 1.

3. Experiments

We test our source and lens reconstruction pipeline using an image of galaxy NGC2906 imaged by the *Hubble* Space Telescope¹ as the mock source. A lensed image of size 500×500 pixels is generated with image side 5 arcmin, corresponding to pixel size of 10 mas. A Gaussian point-spread function kernel is included with FWHM of 5 mas (Simon et al., 2019), although it has minimal effect given the pixel scale. Uniform Gaussian noise is added to the pixels such that the mean signal-to-noise ratio around the lensed ring (defined as pixels that are at least 50% as bright as the brightest pixel) is $\text{SNR} \sim 60$. The lens parameters used to simulate the mock image are chosen as $\{\theta_E, \theta_{x,0}, \theta_{y,0}, \epsilon_1, \epsilon_2, \gamma_1, \gamma_2\} = \{1.3'', 0.1'', 0.0'', 0.2, 0.1, -0.02, 0.02\}$.

The results of our source and lensed image reconstruction

are shown in Fig. 2, with all results normalized to the standard deviation of observation noise. The reconstructed source (b) is seen to provide a visually good representation of the unlensed galaxy (a). The reconstructed lensed image (e) again faithfully reproduces the observed lensed image (d), additionally corroborated by the normalized residuals (f). Some significant residual structures in the source plane are observed in (c); this can at least partially be attributed to a simplistic choice of source pixelization, discussed below. Example reconstructions for additional mock source and lens configurations are presented in App. B.

Figure 3 shows the 1-D and 2-D joint marginal posteriors inferred for the lens and external shear parameters in our experiment. 1-D marginals are shown as Gaussian profiles, while the 2-D joint distributions are represented through their 1- and 2- σ containment regions. The true simulated parameters are indicated with grey lines. Successful recovery of the lens parameters within modeled uncertainty is seen in all cases.

4. Discussion and Future Work

In this ongoing work, we have explored the use of continuous neural fields for modeling morphologically complex gravitationally lensed galaxies. Our method is able to provide a probabilistic reconstruction of lensed galaxies with complex small-scale structure within minutes of wall-clock time, while simultaneously inferring a posterior over the parameterized macroscopic lens deflector field. Although our results are encouraging, practical deployment of the method will require several extensions and modifications to the framework. We conclude by discussing these extensions alongside caveats associated with the proposed method.

In our method, the prior over the source reconstruction is implicit, and it occurs through two separate mechanisms. First, it is affected by the bandwidth limit used in the positional encoding. Second, a low-frequency bias occurs through early stopping of the optimization process, which prevents the neural network from fitting higher-frequency features and overfitting on noise. Although the dynamics associated with this phenomenon have been well-studied (Roberts et al., 2022), a dedicated understanding in the context of our specific domain could inform more principled regularization for a given lens observation configuration. Empirically, we found that excessive optimization leads to overfitting on noisy images, which in turn can produce systematic biases in the reconstruction of lens galaxy parameters.

The positional encoding used in this paper is non-isotropic under rotation, because it processes the two axes independently from each other. An isotropic alternative is random Fourier features (RFF, see Rahimi & Recht (2008)), which samples a projection matrix from an isotropic distribution

¹<https://esahubble.org/images/potw2015a/>

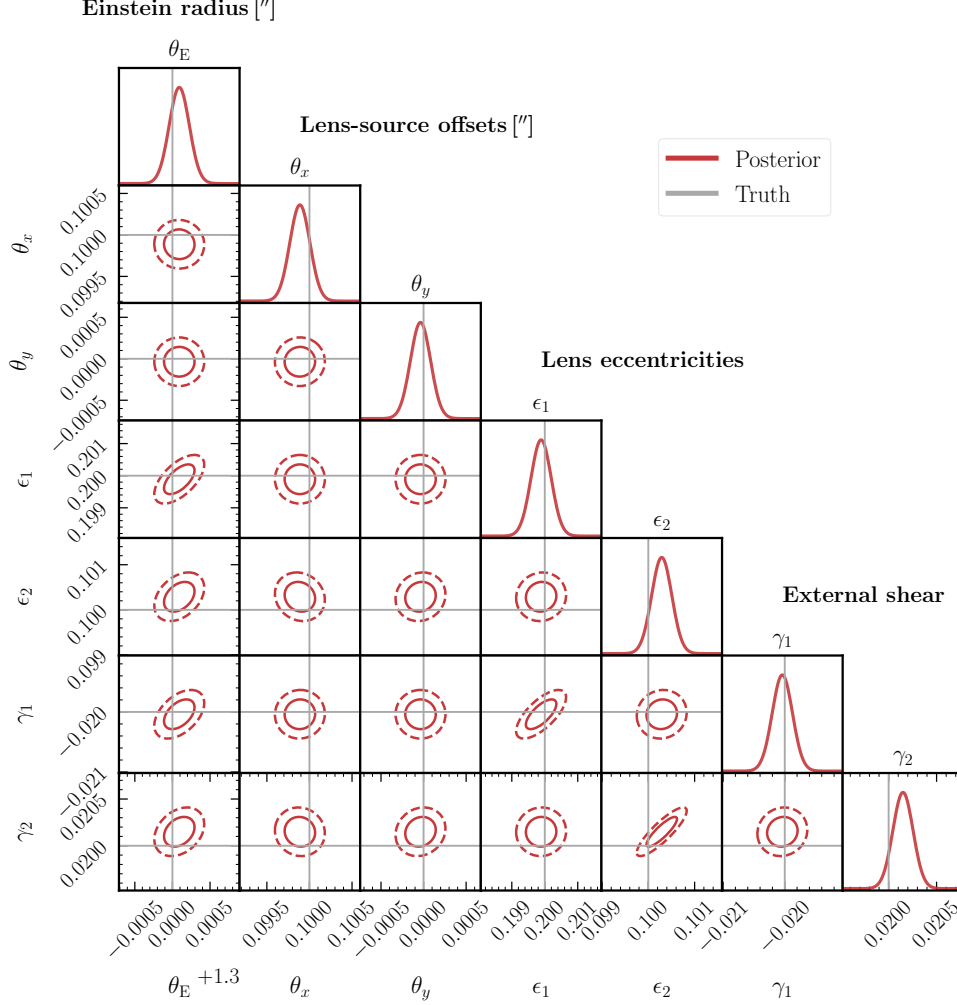

Figure 3. Individual and joint marginal posteriors on the SIE lens galaxy and external shear parameters obtained in our experiment. The ellipses show the 1- and 2- σ containment of the joint posteriors. True parameter points from which the lensed image was simulated are indicated with grey lines. Faithful recovery of the true parameters is seen.

such as a multivariate Gaussian (Yang et al., 2022). Random Fourier features treat the input coordinates as full vectors during the spectral projection. The downside is due to its statistical nature, RFF require a larger number of features. The cut-off band-limit of both encodings can be controlled explicitly through the spectral mixture used to lift the input. In a learned variant of RFF, called the learned Fourier features, these weights are updated through gradient descent. This means more careful regularization of the cut-off bandwidth of the projection matrix is needed.

Modifications to the lensing pipeline can further improve the quality and robustness of reconstruction. For example, the current implementation glosses over subtleties associated with the source-plane pixelization. Instead, it models the pixelated data in the lens plane through individual points in the source plane. In addition, representing the source plane with the same resolution as the lens plane has been shown

to be sub-optimal given the coordinate distortion inherent to the lensing process (Warren & Dye, 2003); the contribution of source-plane regions corresponding to larger magnification should be evaluated at a relatively finer resolution. Our continuous, rather than discretely-sampled, representation of the source should make our framework amenable to a more principled treatment of the source-plane pixelization.

Finally, we could use more expressive variational distributions beyond the Gaussian ansatz and explicitly model covariances between the source galaxy and lens parameters. This could be accomplished, for example, by modeling the lens parameters using a normalizing flow conditioned on summary features extracted from the reconstructed source over the course of optimization. Having demonstrated the potential of the method in a proof-of-principle setting, we leave these extensions to future work.

Software and Data

Code for reproducing the results presented in this paper is available at <https://github.com/smsharma/lensing-neural-fields>. This research made use of the Flax (Heek et al., 2020), gigaLens (Gu et al., 2022), IPython (Pérez & Granger, 2007), Jax (Bradbury et al., 2018; Babuschkin et al., 2020), jaxinterp2d (Coogan), Jupyter (Kluyver et al., 2016), Matplotlib (Hunter, 2007), NumPy (Harris et al., 2020), numpyro (Phan et al., 2019), Optax (Hessel et al., 2020), scikit-image (van der Walt et al., 2014), SciPy (Virtanen et al., 2020), and software packages.

A. Role of positional encodings

Figure 4. Source (top row) and lens (bottom row) reconstruction using variations on mapping the input coordinates to a higher-dimensional feature space. The ground truth (first column), no coordinate mapping (second column), positional encodings (third column; baseline), and Gaussian random Fourier features (last column) are shown. Poor reconstruction of small-scale source galaxy features is seen when not employing an input mapping.

Mapping the input source coordinates into a specific higher-dimensional feature space encourages effective reconstruction of small-scale (high-frequency) features in the source galaxy. This is demonstrated in Fig. 4, where we show the baseline reconstructed source along with a zoom-in inset (top row) and lens (bottom row) for various mapping configurations. The ground truths (first column), results with no coordinate mappings (second column), and standard sinusoidal positional encodings (Eq. (2) with bandwidth hyperparameter set to $L_{\max} = 5$; third column) are shown. It can be seen that small-scale galaxy features are better reconstructed when using positional encodings, whereas these appear washed out without the additional encoding step.

Additionally, we show results using a Gaussian random Fourier feature mapping (Tancik et al., 2020; Rahimi & Recht, 2007; Yang et al., 2022). Here, the source coordinates β are lifted through the mapping $\text{RFF}(\beta)_i = \sin(w_{ij}\beta_j + b_i)$ where the weights and biases are drawn as $w_{ij} \sim \mathcal{N}(0, (B/2)^2)$ and $b_i \sim \mathcal{U}(-1, 1)$ at initialization. The last column of Fig. 4 shows results when using this mapping, setting the bandwidth hyperparameter $B = 5$. Similar performance in reconstructing small-scale galaxy features to that obtained using the standard positional encoding scheme can be seen in this case.

B. Additional examples

In Fig. 5 we show additional source reconstruction results on mock images simulated using images of galaxies NGC1300² and UGC6309³ taken by *Hubble*. The same lens configuration as in the baseline example is used in the first case, while in the second case we set $\{\theta_E, \theta_{x,0}, \theta_{y,0}, \epsilon_1, \epsilon_2, \gamma_1, \gamma_2\} = \{1.1'', 0.4'', -0.1'', 0.1, 0.15, -0.03, 0.04\}$.
